1 **ABSTRACT**

2 To identify novel candidate intellectual disability genes, we performed a meta-analysis on 2,637 *de novo*
3 mutations, identified from the exomes of 2,104 ID trios. Statistical analyses identified 10 novel candidate
4 ID genes, including *DLG4*, *PPM1D*, *RAC1*, *SMAD6*, *SON*, *SOX5*, *SYNCRIP*, *TCF20*, *TLK2* and *TRIP12*. In
5 addition, we show that these genes are intolerant to non-synonymous variation, and that mutations in
6 these genes are associated with specific clinical ID phenotypes.

1 **MAIN TEXT**

2 Intellectual disability (ID) and other neurodevelopmental disorders are in part due to *de novo* mutations
3 affecting protein-coding genes.¹⁻⁴ Large scale exome sequencing studies of patient-parent trios have
4 efficiently identified genes enriched for *de novo* mutations in cohorts of individuals with ID compared to
5 controls,² or based on expected gene-specific mutation rates.⁵

6 Here we sequenced the exomes of 820 patients with intellectual disability and their parents as part of
7 routine genetic testing at the RadboudUMC in the Netherlands. We identified 1,083 *de novo* mutations
8 (DNMs) in the coding and canonical splice site regions affecting 915 genes (**Supplementary Tables 1-2,**
9 **Supplementary Figures 1-4**). In our cohort we detected an increased number of Loss-of-function (LoF)
10 mutations compared to controls (Fisher's exact test $p=9.38 \times 10^{-12}$, **Supplementary Methods**), and
11 enrichment for recurrent gene mutations (observed vs. expected, $p < 1 \times 10^{-5}$, **Supplementary Figure 5**).

12 Based on an established framework of gene specific mutation rates⁶, we calculated for each gene the
13 probability of identifying the observed number of LoF or functional DNMs in our cohort (**Supplementary**
14 **Methods**). To validate this approach we first performed the analysis on the complete set of 820 ID
15 patients. After Benjamini-Hochberg correction for multiple testing, 18 well-known ID genes were
16 significantly enriched for DNMs (**Supplementary Table 3 and 4**). To optimize our analysis for the
17 identification of novel candidate genes in the RUMC cohort, we removed all individuals with mutations
18 in any of the known ID genes (**Supplementary Methods, Supplementary Figure 6**). Repeating the
19 analysis for mutation enrichment, we identified 4 genes (*DLG4*, *PPM1D*, *SOX5*, *TCF20*) not previously
20 associated with ID to be significantly enriched for DNMs in our cohort (**Figure 1, Table 1, Supplementary**
21 **Table 5**). To achieve the best possible power for the identification of novel candidate ID genes, we next
22 added data from 4 previously published family-based sequencing studies (**Supplementary Table 1**). The
23 combined cohort included 2,104 trios and 2,637 DNMs across 1,990 genes. After again excluding
24 individuals with mutations in known ID genes, this cohort consisted of 1,471 individuals with 1,400
25 DNMs in 1,235 genes (**Supplementary Methods, Supplementary Figure 6**). Meta-analysis on this
26 combined cohort identified 10 novel candidate ID genes with more LoF, or more functional, DNMs than
27 expected *a priori*. These 10 genes included the four novel candidate ID genes previously identified in the
28 RUMC cohort, as well as *RAC1*, *SMAD6*, *SON*, *TLK2*, *TRIP12* and *SYNCRIP* (**Figure 1, Table 1,**
29 **Supplementary Table 6**).

30 To further evaluate the identification of the 10 novel candidate ID genes, we compared the phenotypes
31 of the 18 RUMC individuals with DNMs in these genes. We observed strong phenotypic overlap for some
32 of these genes (**Figure 2, Supplemental case reports, Supplementary Table 7**). Further genes, such as
33 *SETD2*, which are close to statistical significance, show phenotypic similarities suggestive for a shared
34 genetic cause consistent with previous case reports^{7, 8} (**Supplementary Figure 7, Supplemental Case**
35 **reports**).

36
37 Studies have shown that genes involved in genetic disorders exhibit strongly reduced tolerance to
38 genetic non-synonymous variation compared to non-disease genes. This is particularly evident for ID.³

1 We found that a large set of well-known dominant ID genes ($n=444$), as well as the 10 novel candidate
2 ID genes are highly intolerant to LoF variation⁹ (Median pLI of 0.95; $p<1\times 10^{-5}$ and 0.99 ; $p<1\times 10^{-5}$
3 respectively; **Supplementary Methods, Supplementary Figure 8** and **Supplementary Table 8**).
4 Intriguingly, we noted that those known and novel candidate dominant ID genes that harbor only
5 missense variants are among the most intolerant ID genes (Median pLI of 0.99; $p<1\times 10^{-5}$;
6 **Supplementary Figure 8**). Additionally, we find that mutations in ‘missense only’ genes are more likely
7 to cluster than mutations in genes for which we also identified LoF mutations ($p=0.01$, Fisher’s exact
8 test; **Supplementary Methods, Supplementary Table 9**).

9 There is considerable overlap of genes and molecular pathways involved in neurodevelopmental
10 disorders (NDDs) such as autism spectrum disorder (ASD), schizophrenia (SCZ), epileptic encephalopathy
11 (EE) and ID.¹⁰ Therefore we performed a third analysis including 12 published family-based sequencing
12 studies of various NDDs (**Supplementary Table 1, Supplementary Figure 6**). Repeating our analysis in
13 this NDD cohort, we identified 7 genes significantly enriched for either LoF or functional DNMs
14 (**Supplementary Figure 9, Supplementary Table 10**). In line with our hypothesis, five of the identified
15 genes were also identified in our previous analyses with individuals with ID only, whereas two genes
16 (*SLC6A1* and *TCF7L2*) only reached significance in the NDD meta-analysis due to additional mutations in
17 patients with other phenotypes than ID (**Supplementary Table 11**). In more detail, for two of the five
18 candidate ID genes (*TLK2* and *TRIP12*) additional *de novo* mutations were identified in individuals with
19 ASD and SCZ, suggesting that DNMs in these genes may lead to a broader phenotype than only ID. For
20 *TRIP12*, a similarly broad phenotype has been reported previously.⁴

21 In summary, we identified 10 novel candidate ID genes in a meta-analysis of WES data on 2,104 ID trios.
22 The statistical framework used here, differs from existing methods based on gene specific mutation
23 rates, by removing all trios with mutations in known disease genes, and by applying Benjamini-Hochberg
24 correction for multiple testing. Our study underscores the impact of *de novo* mutations on a continuum
25 of neurodevelopmental phenotypes, that impinge on a broad range of processes including chromatin
26 modifiers (*TRIP12*, *TLK2*), FMRP target and synaptic plasticity genes (*DLG4*; **Supplementary Figure 10**)
27 and embryonically expressed genes (*PPM1D*, *RAC1*)². Data from a similar systematic study of *de novo*
28 mutations in neurodevelopmental disorders suggest that many, and possibly most, genes causing severe
29 developmental disorders by *de novo* mutation are now known¹¹. Yet, only *TCF20* and *PPM1D* are shared
30 between the 10 novel genes in our study and the 14 genes identified by McRae and colleagues. Thus, a
31 large number of rare dominant developmental disorder genes may remain to be identified.

3 **Table 1.** Novel candidate ID genes. All genes listed reached statistical significance after Benjamini-
4 Hochberg correction for enrichment of functional and/or loss-of-function (LoF) DNM in the RUMC or ID
5 cohort. For each gene the Benjamini-Hochberg corrected p-value (**q**), uncorrected p-value (**p**) and the
6 raw counts (**c**) are shown.

7

1 **Online Methods**

2 **Recruitment of individuals with ID**

3 The Department of Human Genetics from the Radboud University Medical Center (RUMC) is a tertiary
4 referral center for clinical genetics. Approximately 350 individuals with unexplained intellectual disability
5 (ID) are referred annually to our clinic for diagnostic evaluation. Since September 2011 whole exome
6 sequencing (WES) is part the routine diagnostic work-up aimed at the identification of the genetic cause
7 underlying disease.¹² For individuals with unexplained ID, a family-based WES approach is used which
8 allows the identification of *de novo* mutations as well as variants segregating according to other types of
9 inheritance, including recessive mutations and maternally inherited X-linked recessive mutations in
10 males.¹³ For the purpose of this study, we selected all individuals with ID who had family-based WES
11 using the Agilent SureSelect v4 enrichment kit combined with sequencing on the Illumina HiSeq platform
12 in the time period 2013-2015. This selection yielded a set of 820 individuals, including 359 females and
13 461 males. The level of ID ranged between mild (IQ 50-70) and severe-profound (IQ<30).

14 Families gave informed consent for both the diagnostic procedure as well as for forthcoming research
15 that could result in the identification of new genes underlying ID by meta-analysis, as presented here.
16 Explicit consent for photo-publication was sought and given by a subset of families.

17 **Diagnostic whole exome sequencing**

18 The exomes of 820 patient-parent trios were sequenced using DNA isolated from blood, at the *Beijing*
19 *Genomics Institute* (BGI) in Copenhagen. Exome capture was performed using Agilent SureSelect v4 and
20 samples were sequenced on an Illumina HiSeq instrument with 101bp paired-end reads to a median
21 coverage of 75x. Sequence reads were aligned to the hg19 reference genome using BWA version 0.5.9-
22 r16. Variants were subsequently called by the GATK unified genotyper (version 3.2-2) and annotated
23 using a custom diagnostic annotation pipeline. Base-pair resolution coverage of the regions enriched by
24 the SureSelect V4 kit are computed by BEDTools based on the regions as provided by the manufacturer.
25 An average 98.9% of Agilent SureSelect V4 enriched targets was covered by 10 or more reads for the
26 RUMC cohort of 820 ID patients (**Supplementary Figure 1**).

27 **Identification of *de novo* mutations in 820 individuals with ID**

28 The diagnostic WES process as outlined above only reports (*de novo*) variants that can be linked to the
29 individuals' phenotype. In this study, we systematically collected all *de novo* mutations located in coding
30 sequence (RefSeq) and/or affected canonical splice sites (canonical dinucleotides GT and AG for donor
31 and acceptor sites; **Supplementary Figure 4**), identified in 820 individuals with ID irrespective of their
32 link to disease, to evaluate the potential relevance of genes for ID in an unbiased fashion using a
33 statistical framework. *De novo* mutations were called as described previously.¹³ Briefly, variants called
34 within parental samples were removed from the variants called in the child. For the remaining variants
35 pileups were generated from the alignments of the child and both parents. Based on pileup results
36 variants were then classified into the following categories: "maternal (for identified in the mother
37 only)", "paternal (for identified in the father only)", "low coverage" (for insufficient read depth in either

1 parent), “shared” (for identified in both parents)”, and “possibly *de novo*” (for absent in the parents).
2 Variants classified as “possibly *de novo*” were included in this study.

3 We applied various quality measures to ensure that only the most reliable calls were included in the
4 study: (i) all samples had less than 25 “possibly *de novo*” calls; (ii) the variant had at least 10x coverage
5 in either parent (e.g. high prior probability of being inherited); (iii) the location was not known in dbSNP
6 version137 (e.g. possible highly mutable genomic location) and (iv) was identified in a maximum of 5
7 samples in our in-house variant database (e.g. eliminating variants that are too frequent to be disease-
8 causing given the incidence of ID in combination with the sample size of our in-house database); and (v)
9 each variant showed a variant read percentage >30%, or alternatively, >20% with >10 individual variant
10 reads and (vi) a GATK quality score of >400. For *de novo* variants called within a 5bp window of each
11 other within the same individual, variant calls were manually curated and merged into a single call
12 (when occurring on the same allele). This set of criteria resulted in the identification of 1,083 potential
13 *de novo* mutations in 820 individuals with ID.

14 **Validation and categorization of *de novo* mutations**

15 In a separate (unpublished) in-house study, we recently determined the predictive value for GATK
16 quality scores in terms of the variant being validated by Sanger sequencing. A set of 840 variants called
17 by the same version of GATK was retrospectively analyzed for their respective quality scores and
18 validation status. Based on this assessment, we determined that a GATK quality score ≥ 500 resulted in
19 100% of variants being validated by Sanger sequencing (data not shown; internal reference VAL G 084).
20 In addition to our in-house study two other studies also found a 100% Sanger validation rate for the
21 variants with a GATK quality score of ≥ 500 .¹⁴ Based on this we considered all variants with a GATK Q-
22 score of ≥ 500 (n=1,039) to be true *de novo* mutations. Nonetheless, a random set of 141 potential *de*
23 *novo* mutations with GATK Q-scores of ≥ 500 were all confirmed by Sanger sequencing. All potential *de*
24 *novo* variants with a GATK Q-score between 400-500 (n=40) were subsequently validated by Sanger
25 sequencing, and all were confirmed. All 20 *de novo* mutations of the reported novel candidate genes
26 were confirmed by Sanger sequencing (**Supplementary Table 2, Supplementary Figures 2-4**).

27 For further downstream statistical analysis (see below), DNMs were categorized by mutation type: (i)
28 **loss-of-function (LoF) DNM (n=211)**, including nonsense (n=77), frameshift (n=97), canonical splice site
29 (n=27), start loss (n=2), stop loss (n=1), premature stop codon resulting from an indel (n=7); (ii)
30 **functional DNM (n=872)**, including all LoF mutations (n=211), in-frame insertion/deletion events (n=23)
31 and all missense mutations (n=638) (**Supplementary Figure 4**). For variants within the same individual
32 and within the same gene but more than 5bp apart, the variant with the most severe functional effect
33 was considered for the per gene statistics (see below).

34 **Evaluating the number of recurrently LoF and functional *de novo* mutated genes**

35 We simulated the expected number of recurrently mutated genes by redistributing the observed
36 number of mutations at random over all genes based on their specific loss-of-function (LoF, see section
37 “Statistical enrichment of DNMs”) and functional mutation rates (see section “Statistical enrichment of
38 DNMs”) as described by Samocha *et al.*⁶ Based on 100,000 simulations we calculated how many times

1 the number of recurrently mutated genes was the same or exceeded the observed number of
2 recurrently mutated genes in the RUMC dataset. We performed the simulation separately for LoF and
3 functional DNMs (**Supplementary Figure 5**). P-values were then calculated by taking the number of
4 times the number of recurrently mutated genes exceeded the observed number of recurrently mutated
5 genes, divided by the number of simulations.

6 **Genes previously implicated in ID etiology**

7 To evaluate whether the genes identified by our meta-analyses have been implicated in ID before, two
8 publicly available repositories of genes known to be involved in ID were used. Firstly, we used our list of
9 707 genes, routinely used by our diagnostic setting to interpret WES results of individuals with ID.¹⁵
10 Secondly, we downloaded a list of 1,424 genes from the DDG2P database reflecting genes to be
11 associated with developmental disorders, which has been compiled and curated by clinicians as part of
12 the DDD study to facilitate clinical feedback of likely causal variants.⁵ In total the two lists comprised
13 1,537 unique genes. In this manuscript, the list of unique gene entries is referred to as known ID genes
14 (**Supplementary Table 4**).

15 **Statistical enrichment of DNMs**

16 In our meta-analysis for ID and neurodevelopmental disorders we only included studies with minimum
17 of 50 trios. For each gene, and each of the functional classes (LoF and functional) ,we used the
18 corresponding gene specific mutation rate (GSMR) as published by Samocha *et al.* (2014)⁶ to calculate
19 the probability of the number of identified *de novo* mutations in our cohort. For genes for which no
20 GSMR was reported, we used the maximum GSMR of all reported genes (*i.e.* the GSMR of the gene *TTN*).
21 We then calculated specific mutation rates for the two defined functional classes (loss-of-function,
22 functional). The GSMR for loss-of-function DNMs was calculated by summing the individual GSMR for
23 nonsense, splice site and frame-shift variants; The GSMR for functional DNMs was calculated by
24 summing the GSMR for the loss-of-function (LoF) variants with the missense mutation rate; and for
25 genes for which variants from different functional classes were identified, we used the overall GSMR.
26 For the stoploss and startloss mutations we used the LoF-rate and for in-frame indels the functional
27 rate. Null hypothesis testing was done using a one-sided exact Poisson Test based on a sample size of
28 820 individuals with ID, representing 1,640 alleles for autosomal genes, and 1,179 alleles for genes on
29 the X-chromosome (461 males).

30 For DNMs on chromosome X the correct mutation rate depends on the patient's gender as the mutation
31 rates for fathers is higher than for mothers. Estimates show a 4:1 ratio of paternal to maternal *de novo*
32 mutations¹⁶. Hence, male offspring, receiving their chromosome X exclusively from the mother, have
33 therefore a lower mutation rate on chromosome X than estimated by the GSMR. This correction could
34 however only be performed for the RUMC cohort, as information of gender was not available for all
35 studies included in the ID cohort. Of note, not correcting for this bias in male individuals for DNM in
36 genes on the X chromosome, however will lead to less significant p-values for genes on the X-
37 chromosome, thereby potentially underestimating the significance of candidate novel ID genes located
38 on the X-chromosome. In the case where one patient has two DNMs in the same gene we ignored one

1 of the two DNMs for the statistical enrichment analysis to avoid false positive results. In the
2 aforementioned case the severity of the DNM protein-effect was used in the choice which DNM to
3 ignore. For example, if a patient has one missense and one nonsense DNM in the same gene the
4 missense mutation was ignored in the statistical analysis.

5 The gene specific p -values were corrected for multiple testing based on the 18,730 genes (present in the
6 Agilent V4 exome enrichment kit) times the number of tests (x2), using the Benjamini-Hochberg
7 procedure with an FDR of 0.05. In our cohort of 820 individuals with ID, conclusive diagnosis were
8 already made based on DNMs in a genes previously implicated in disease. The use of a multiple testing
9 correction with a FDR of 0.05, in combination with a potential large number of DNMs in known ID genes
10 may cause the artificial significance of other genes because of an increasing lenient correction for the
11 least significant genes¹⁷. To verify that the identification of novel candidate ID genes is not inflated by
12 this effect, we performed the analysis after removing all individuals with a DNM in one of the known
13 genes (potential other DNMs in such individuals were also removed for further analysis). Incidentally,
14 this also increased our statistical power. The mode of inheritance was not taken into account when
15 removing individuals with a DNM in a known gene (e.g. samples with a DNM in a recessive gene were
16 excluded). This correction left 584/820 individuals with ID in the RUMC cohort, with 627 DNMs across
17 584 genes. Similarly, for the ID and neurodevelopmental cohort, we removed all individuals with a DNM
18 in a known ID gene (and other DNMs in these individuals). For the ID cohort, 1,471 samples remained
19 with 1,400 DNMs in 1,235 genes. For the neurodevelopmental cohort, 4,944 samples with 4,387 DNM
20 across 3,402 genes remained (For the complete overview see **Supplementary Figure 6**). We corrected
21 for testing 34,386 genes (*i.e.* all 18,730 genes minus the 1,537 known ID genes multiplied by two for
22 testing the loss-of-function and functional categories).

23 **Validation of the statistical approach by analysis of DNMs in a control cohort**

24 To further confirm the validity of our statistical approach, we applied the same analyses to a set of
25 DNMs identified in trios of healthy individuals and unaffected siblings. Hereto, we downloaded and re-
26 annotated all DNMs identified in 1,911 unaffected siblings of individuals with ASD from Iossifov *et al.*²
27 together with DNMs in controls (**Supplementary Table 14**). In total the control set contained 2,019
28 coding DNMs found in 2,299 trios. Of note, the protein coding *de novo* mutation rate in the control
29 cohort was markedly lower than observed in the individuals with ID (0.91 vs. 1.32, respectively).
30 Additionally, we observed no significant enrichment of recurrently mutated genes for loss-of-function or
31 functional mutations ($p=0.60$ and $p=0.12$, respectively, **Supplementary Figure 11**).

32 For the control cohort we performed the statistical analysis as described above and identified only one
33 gene to be significantly enriched for DNMs. For *YIF1A* (FDR corrected p -value = 0.01) we identified a
34 total of 3 missense and 1 frame-shift DNM (**Supplementary Table 13-14**). *YIF1A* may be involved in
35 transport between the endoplasmic reticulum and the Golgi, and has a pLI (probability of being loss-of-
36 function intolerant) of 2.08×10^{-8} indicating this gene is a loss-of-function tolerant gene. We note that the
37 control cohort consists mostly of healthy siblings from individuals with ASD, and, as such, may still have
38 a small enrichment for mutations that lead to susceptibility for neurodevelopmental disorders.

1 **Increased number of Loss-of-function (LoF) mutations in RUMC cohort compared to controls**

2 To reduce the impact of the used enrichment kit used in the control set studies and RUMC cohort we
3 computed the intersection of all enrichment kits (Agilent SureSelect 37Mb \cap Agilent SureSelect 50Mb \cap
4 Agilent SureSelect V4 \cap Nimblegen SeqCap V2; see **Supplementary Table 12**) via the 'intersect' function
5 of BEDTools. Only the loss-of-function *de novo* mutations present in the 28,189,737 Mb intersection of
6 the four enrichment kits were used in the analysis. The Fisher's exact test on the enrichment kits
7 normalized loss-of-function *de novo* mutations yielded a significant difference with p-value= 9.38×10^{-12}
8 (RUMC: 157 LoF *de novo* mutations of a total of 805 *de novo* mutations; control set: 137 LoF *de novo*
9 mutations of a total of 1,485 *de novo* mutations). The coverage and other relevant technical information
10 of the control studies are enlisted in **Supplementary table 12**. We note it is important to take into
11 account the coverage and false negative rates of all sequencing studies. So far, only a single study has
12 attempted to provide a false negative rate (e.g. mutations that are there but were not identified) for
13 exome sequencing, and this was predicted to be $<5\%^2$.

14 **Attributing pLI for all protein coding genes**

15 To determine the intolerance to loss-of-function (LoF) variation for each gene, we used the pLI which is
16 based on data from the Exome Aggregation Consortium (ExAC) version 0.3.1 providing exome variants
17 from 60,706 unrelated individuals⁹. The pLI, or the probability of being LoF intolerance, is based on the
18 expected vs. observed variant counts to determine the probability that a gene is intolerant to LoF
19 variants and is computed for a total of 18,226 genes. The closer a pLI is to 1 the more intolerant a gene
20 is to LoF variants. The authors consider a pLI ≥ 0.9 as an extremely LoF intolerant set of genes. The list
21 of the pLI for the genes used in this study can be found in **Supplementary Table 8**. The performance of
22 the pLI was evaluated for four gene sets **1**) 170 Loss-of-function (LoF) tolerant genes¹⁸ **2**) 404 "House-
23 keeping" genes, involved in crucial roles in cell maintenance¹⁹ **3**) 1,359 genes with functional *de novo*
24 mutations from the healthy control dataset (**Supplementary Table 14**); **4**) 444 Well-known dominant ID
25 genes (**Supplementary Table 4**).

26 **Gene set based evaluation of pLI**

27 We evaluated the pLI by computing the expected median pLI for each gene set based on randomly
28 drawing n pLI values from the complete set of 18,226 pLI annotated genes and calculate the median
29 (where n is the number of genes in the gene set). By repeating this random sampling process 100.000
30 times, we can compute the likelihood of the observed median pLI to the expected median pLI by
31 calculating the empirical p-value:

$$\text{empirical p-value} = \frac{(\sum_{i=1}^N m_i > m_{\text{observed}}) + 1}{N + 1}$$

32 where m is the median pLI of one simulation, m_{observed} is the observed median pLI and N is the total
33 number of performed simulations ($N=100.000$). Based on the simulations we identified a significant
34 lower (Observed 9.33×10^{-9} vs. expected 0.03; empirical p-value: $<1 \times 10^{-5}$) median pLI for the loss-of-
35 function tolerant (LoFT) genes which is in line with the LoF tolerant nature of this gene set. For the

1 healthy control set the observed median pLI matched the expected median pLI (Observed 0.03 vs.
2 expected 0.03; empirical p-value: 0.31). For the “house-keeping” and dominant ID gene sets the
3 observed median pLI is significantly higher than the expected median pLI (Observed: 0.87 vs. expected:
4 0.03; empirical p-value $<1 \times 10^{-5}$; Observed: 0.95 vs. expected: 0.03; empirical p-value $<1 \times 10^{-5}$,
5 respectively). The median pLI of the “house-keeping” gene approximates (median pLI = 0.87) and the
6 dominant ID gene set (median pLI = 0.95) surpasses the extremely LoF intolerant threshold of 0.9 which
7 is in line with the LoF intolerant nature for of “house-keeping” and dominant ID genes (**Supplementary**
8 **Figure 12**).

9 The set of ten novel candidate ID genes has a median pLI of 0.99 (Observed 0.99 vs. expected 0.05;
10 empirical p-value $<1 \times 10^{-5}$) which is, as observed for the dominant ID genes, above the extremely LoF
11 gene threshold of 0.9 (**Supplementary Figure 8**). For the 21 dominant ‘missense only’ genes (with at
12 least 3 missense mutations in the absence of LoF mutations) we observe the highest median pLI of
13 0.9999 (Empirical p-value $<1 \times 10^{-5}$) illustrating that those known and novel candidate dominant ID genes
14 that harbor only missense variants are among the most LoF intolerant ID genes (**Supplementary Figure**
15 **8**).

16 **Attributing Residual Variation Intolerance Score (RVIS) for all genes**

17 In addition, the Residual Variation Intolerance Score (RVIS) were assessed for the same gene sets as for
18 the aforementioned pLI. The RVIS ranks genes based on whether they have more or less common
19 functional genetic variation relative to the genome-wide expectation. The initial RVIS gene scores were
20 computed based on the NHLBI-ESP6500 data set²⁰ and recently recomputed based on the ExAC v0.3
21 dataset (<http://genic-intolerance.org/>). The genes from our study were annotated with the RVIS scores
22 based on ExAC (**Supplementary Table 8**).

23 RVIS scores for gene sets were compared in the same way as for the pLI (**Supplementary Figure 13**).
24 Again, we found the set of ten novel candidate ID genes to be significantly more intolerant than any
25 random set of genes found (empirical p-value = 4.60×10^{-4}), similar to the known dominant ID genes
26 (**Supplementary Figure 13**). For the 21 dominant ‘missense only’ genes we again observe the lowest
27 median RVIS of 3.56 (Empirical p-value $<1 \times 10^{-5}$; **Supplementary Figure 13**).

28

29 **Estimating clustering of *de novo* mutations**

30 The spatial distribution of missense, frame-shifts and nonsense DNMs were analyzed for clustering
31 within the respective gene they occurred based on 100,000 simulations. The locations of observed
32 DNMs were randomly sampled over the coding exons of the gene and the distances (in base pairs)
33 between the mutations were normalized for the total coding size of the respective gene. The geometric
34 mean (the n^{th} root of the product of n numbers) of all mutation distances between the DNMs was taken
35 as a measure of clustering. A pseudo count (adding one to all distances and one to the gene size) was

1 applied to avoid a mean distance of 0 when there are identical mutations and ignoring the distances to
2 the remaining DNMs.

3 Based on the prior distance distribution of the 100,000 simulations, a gene-based empirical probability
4 of the observed distance was computed for dominant ID genes with 3 or more DNMs (n=64 genes) in
5 the ID set of 2,104 trios. A total of 21 genes contained only missense mutations (“missense only” group)
6 and 43 genes contained frame-shift, nonsense or a combination of frame-shift, nonsense and missense
7 DNMs (“LoF + Functional” group). In 21 genes of the “missense only” group five genes had an empirical
8 probability below the significant threshold of 0.05/64, whereas only one of the 43 “LoF + Functional”
9 genes had a empirical probability below the significant threshold (**Supplementary Table 9**). Fisher’s
10 exact test was used to compute the statistical significance.

11 **Clinical evaluation of selected patients**

12 All patients were referred by clinical geneticists for diagnostic evaluation and overall patient
13 characteristics were comparable to a previously published cohort¹³. To confirm the identification of the
14 novel candidate ID genes, we compared the phenotypes of individuals with a DNM in any one of the 10
15 novel candidate genes and two genes (*SLC6A1* and *TCF7L2*) significantly enriched in the
16 neurodevelopmental cohort. Comparison of phenotypes was only possible for 8/12 genes in which at
17 least two individuals with ID were in the RUMC cohort (7/10 novel candidate ID genes, and 1/2 novel
18 candidate NDD genes). Detailed clinical information of other published individuals is mostly not
19 available. A table listing these clinical details is provided in **Supplementary Table 7**. For *TLK2* and *SETD2*
20 a more detailed phenotypic comparison was performed (see case reports below).

3 **TLK2**

4 *Patient 17*

5 This male is the second of three children of consanguineous parents of Turkish ancestry. His father had
6 learning difficulties and was illiterate. He was born after 40+3 weeks of gestation with a birth weight of
7 3415 gram (0 SD), length of 50 cm (-2 SD) and head circumference of 35 cm (0 SD). Delivery was
8 uncomplicated. Both motor and language development were delayed. He started walking at the age of 2
9 years. At the age of 20 years, psychological assessment revealed a TIQ level of 56 (WISC-III). He followed
10 special education as a child, but after finishing this, he was not able to work due to severe psychiatric
11 problems with frequent tantrums and periods of hyperventilation. Several psychiatric medications
12 turned out to be insufficient. Ophthalmologic examination revealed myopia (-2.5/-3.5 dioptre) and
13 strabismus of the left eye. He was treated for oesophagitis and had frequent diarrhea. Because of his
14 delayed development, he was referred to a clinical geneticist. Physical examination at the age of 16
15 years showed a normal height of 171 cm (-0.5 SD, based on normal values for Turkish children¹ and
16 normal weight of 50.3 kg (-0.5 SD). He had facial dysmorphisms including short forehead, upward
17 slanting palpebral fissures, mild epicanthal folds, hypertelorism, ptosis, flat mid-face, thin upper lip and
18 pointed chin. Thoracal kyphosis and scoliosis were noticed. His hands showed contractures of the
19 proximal interphalangeal joints of the fourth fingers and absence of flexion creases of the distal
20 interphalangeal joints of the second till fourth fingers. Previous investigations, comprising of
21 karyotyping, fragile X screening and SNP array analysis were normal. Metabolic screening and brain MRI
22 scan, performed at age 16 years, showed no abnormalities. Using whole exome sequencing, a *de novo*
23 *TLK2* mutation was identified: Chr17(GRCh37):g.60678182G>T; NM_006852.3:c.1720+1G>T (p.(r.spl?)).

24 *Patient 439*

25 This male patient is the second of two children of nonconsanguineous parents of Dutch ancestry. There
26 were no developmental problems reported in the family. Prenatal ultrasound showed a single umbilical
27 artery. He was born after 40 weeks of gestation with a birth weight of 3170 gram (-1 SD) after an
28 uncomplicated delivery. As neonate, he had feeding difficulties and low weight. His development was
29 delayed. He started walking at the age of 18 months. He spoke the first words at normal age, but further
30 language development was delayed and he speaks with hoarse voice. Psychological assessment at the
31 age of 5 years showed a borderline TIQ level of 80 and at the age of 7.5 years a mild intellectual
32 disability with a TIQ level of 67 (SON-R 6-40). He was recently diagnosed with multiple complex
33 developmental disorders, with severe problems in regulation of emotions and anxiety. Treatment with
34 Abilify and Cipramil has been started to alleviate the symptoms. The boy had severe constipation,
35 requiring laxatives. Physical examination at the age of 7 years showed a short stature, with a height of
36 11.5 cm (-2.5 SD), normal weight of 21 kg (0 SD) and normal head circumference of 50 cm (-1 SD). He
37 had facial dysmorphisms including upward slanting palpebral fissures, blepharophimosis, ptosis, full
38 nasal tip and pointed chin. His hands showed brachydactyly and single flexion crease of the second and

1 third finger. Previous investigations, consisting of fragile X screening and SNP array, were normal.
2 Metabolic screening showed no abnormalities. Using whole exome sequencing a *de novo* *TLK2* mutation
3 was identified: Chr17(GRCh37):g.60689765C>T; NM_006852.3:c.2092C>T (p.(Arg698*)).

4 **SETD2**

5 *Patient 162*

6 This male patient is the first child of three children of non-consanguineous parents of Dutch ancestry.
7 There were no developmental problems reported in the family. He was born after 36+4 weeks of
8 gestation which was complicated by maternal hypertension and HELLP syndrome. Delivery was
9 uncomplicated. His birth weight of 2625 gram (-1.5 SD) was normal. There was normal motor
10 development, but delayed development of language, with the first words at the age of 3 year. At the age
11 of 7 years, psychological assessment showed mild ID with TIQ of 54 (WISC-III). As child, he received
12 surgery for bilateral inguinal hernia. He needed glasses to correct myopia (-2/-2.5 dioptr). Physical
13 examination at the age of 11 years showed macrocephaly with a head circumference of 59.5 cm (+4 SD),
14 high-normal height of 164.4 cm (+2 SD) and low-normal weight of 45 kg (-2 SD). He had facial
15 dysmorphisms including small and protruding ears, broad forehead, hypertelorism, downward slanting
16 and narrow palpebral fissures. A small scrotum was present. There were no abnormalities of the
17 extremities observed. At age of 4 years, brain MRI and metabolic screening showed no abnormalities.
18 Previous investigations, consisting of karyotyping, MLPA analysis, fragile X screening, 250k SNP array and
19 sequence analysis of multiple genes (*SOS1*, *NRAS*, *SHOC2*, *NF1*, *SPRED1*, *NSD1*, *KCNQ1OT1*, *H19*, *NFIX*,
20 *EZH2*, *BRAF*, *MAP2K1*, *KRAS*, *PTPN11*, *RAF1*) were normal. Using whole exome sequencing a *de novo*
21 *SETD2* mutation was identified: Chr3(GRCh37):g.47161721dup; NM_014159.6:c.4405dup
22 (p.(Met1469fs)).

23 *Patient 716*

24 This male patient was the second of two children of non-consanguineous parents of Dutch ancestry. His
25 older brother needed special education because of severe behavior problems. Further family history
26 was not contributory. He was born after 40 weeks of gestation with a birth weight of 3000 gram (-1.5
27 SD). Delivery was uncomplicated. In the first year, no problems were noticed, but after his first year,
28 both motor and language development were delayed. He walked the first steps at the age of 19 months.
29 As young child, he was aggressive to other children, but this improved from the age of 8 years. He was
30 referred to a clinical geneticist because of developmental delay, tall stature and macrocephaly. From
31 age 9 years, he eats unrestrained and gains weight. Physical examination at the age of 9 years showed
32 tall stature with height of 162.5 cm (+2.5 SD), macrocephaly with head circumference of 57.8 cm (+3 SD)
33 and normal weight of 55.5 kg (+1.5 SD). He had facial dysmorphisms including high forehead, deep set
34 eyes and downward slanting of palpebral fissures. There was clinodactyly of his second and third toes
35 and he had a mastocytoma on his right leg. Brain MRI at the age of 9 years showed a subarachnoid cyst
36 left temporal. Analysis of growth hormones showed no abnormalities, but hand films revealed advanced
37 carpal and phalangeal bone age of 11 years at the age of 9 years. Previous investigations, consisting of
38 karyotyping, fragile X and Sotos screening were normal. Using family-based whole exome sequencing a

1 *de novo* mutation in *SETD2* was identified: Chr3(GRCh37):g.47155435_47155437del;
2 NM_014159.6:c.4644_4646del (p.(Gln1548del)).

(Excel file)

Supplemental Figures

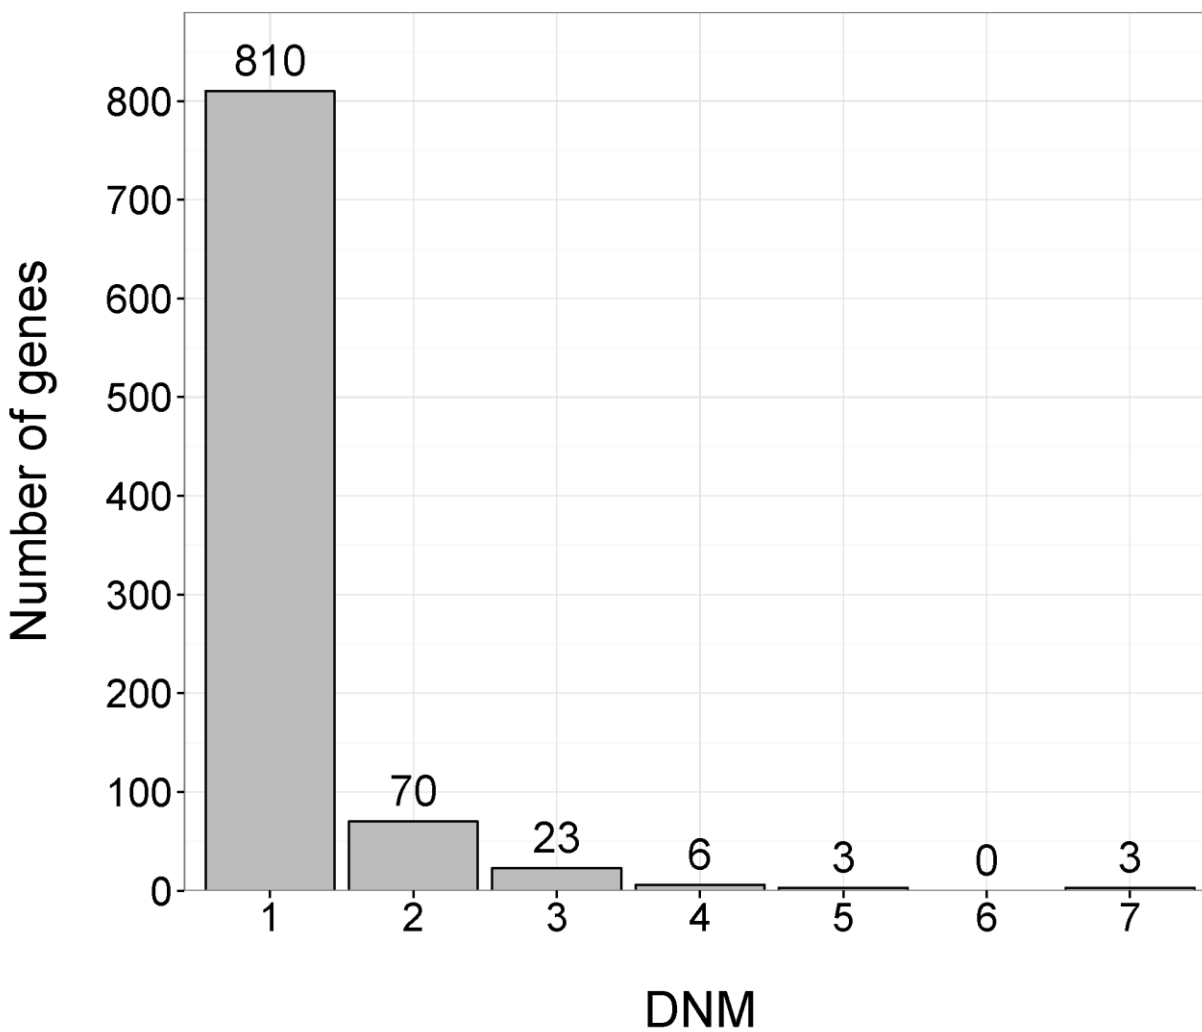

Supplementary Figure 1. Overview of the percentage of on target coverage by 10 or more reads. A scatter plot of the percentage of on target coverage by 10 or more reads shown for the 820 samples of the RUMC cohort. In this figure the samples are ordered ascending based on the percentage of on target coverage. The median percentage of 98.9% on target coverage by 10 or more reads of the RUMC cohort is depicted by the black thick line.

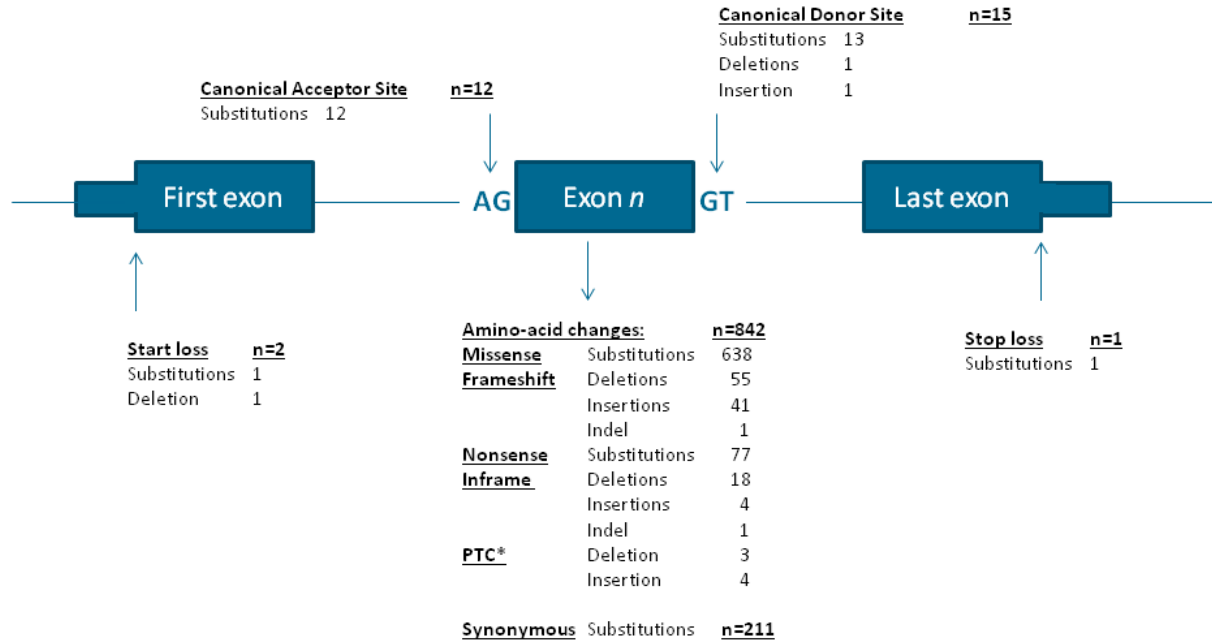

Supplementary Figure 2. Distribution of *de novo* mutations (DNM) over patients in the RUMC cohort.

In total, 619/820 patients had at least one *de novo* mutation.

Supplementary Figure 3. Distribution of *de novo* mutations per gene in the RUMC cohort.

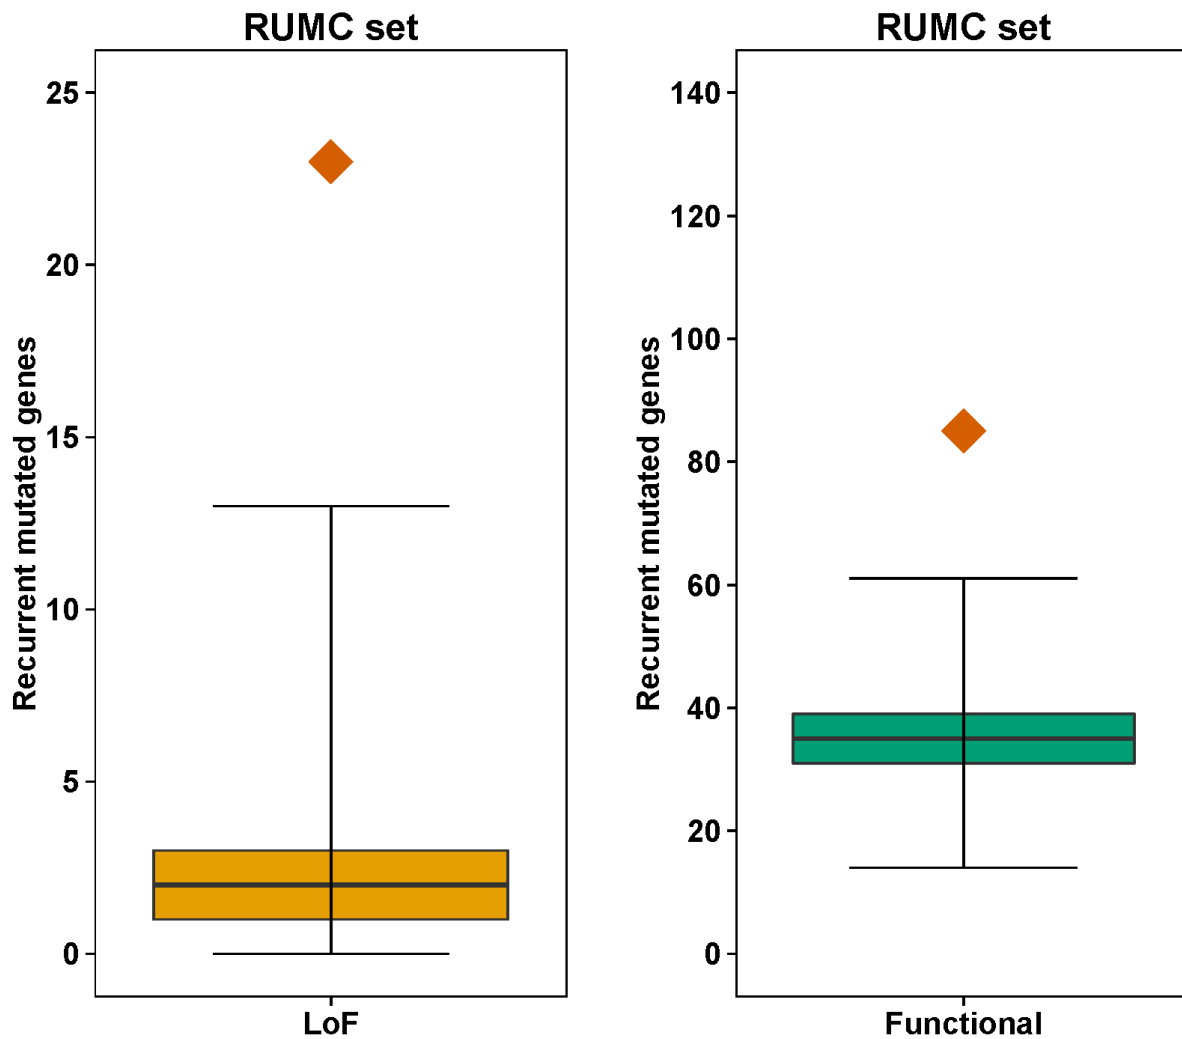

In total, 915 different genes have had at least one *de novo* mutation.

*PTC: premature termination codon resulting from an insertion or deletion event

Supplementary Figure 4. Schematic representation of the location of *de novo* mutations identified in the RUMC cohort and their presumed effect on protein function.

*: Premature Termination Codon (PTC); An insertion or deletion does not introduce a frameshift event, but directly creates a PTC.

Supplementary Figure 5. Simulations of recurrently mutated genes of the RUMC cohort.

The panels show the distribution of the number of recurrently mutated genes based on 100,000 simulations. The colored boxes indicate the interquartile range; the whiskers indicate the full interval (LoF median: 2, range [0,13]; functional median: 35, range [14,61]) and the orange diamond indicate the observed number of recurrent *de novo* mutated genes in 820 ID patients (RUMC-cohort). For the LoF and the functional categories the observed number of recurrently mutated genes (observed LoF: 23; functional: 85) do statistically differ from the simulations based on the gene specific mutation rates of Samocha *et al.* (LoF empirical P-value: $<1.00 \times 10^{-05}$; functional empirical P-value: $<1.00 \times 10^{-05}$).

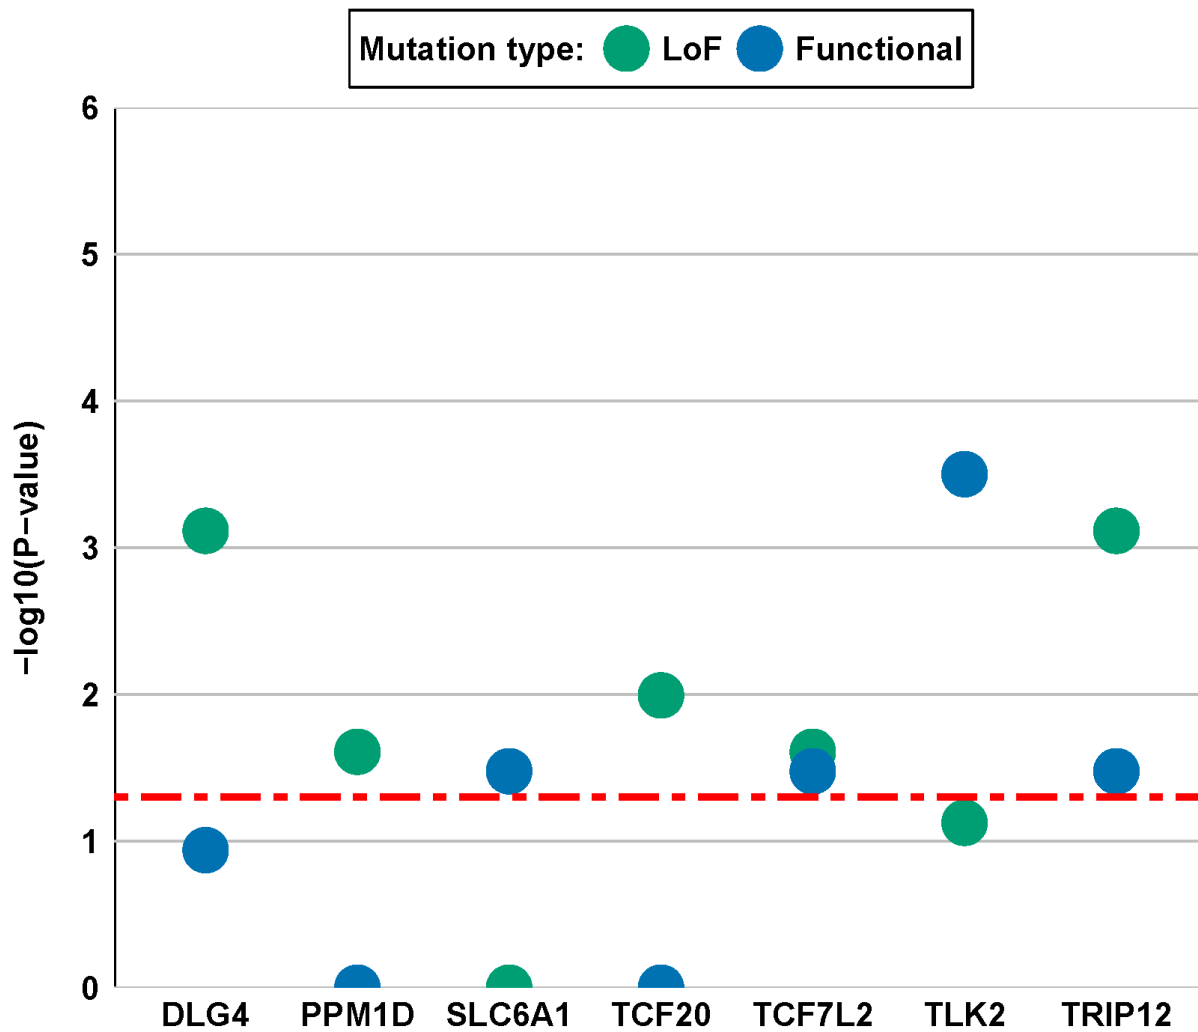

Supplementary Figure 6. Flow chart of cohort construction for statistical analysis. Based on the presence of de novo mutations (DNMs) in 1,537 known ID genes (**Supplementary table 4**) the patients were divided among two groups for **a**) the RUMC cohort (820 trios) **b**) the combined ID cohort (2,104 trios) and **c**) the neurodevelopmental cohort (6,206 trios). The group on the left side in the color red indicate the patients with DNMs found in known ID genes. On the right, in color green, is the group of patients without DNMs present in the 1,537 known ID genes. The statistical analysis was performed on the cohort consisting of patients without DNMs in known genes. The number of trios and DNMs present in genes is shown for each group.

Supplementary Figure 7. SETD2 (Q9BYW2) with *de novo* mutations in individuals with ID and ASD. Individuals show similar overgrowth phenotype including macrocephaly, tall stature and facial dysmorphisms (**Supplemental Case reports**).

Supplementary Figure 8. Intolerance to Loss-of-function (LoF) variation for ID genes. The box plots indicate the median pLI (probability LoF intolerant) for the gene sets based on 100,000 simulation (see **Online Methods**). The red diamonds show the observed median pLI. The closer a pLI is to 1 the more intolerant a gene is to LoF variants. A pLI ≥ 0.9 is considered as an extremely LoF intolerant set of genes²¹. The genes with at least one functional *de novo* mutation in healthy control set (Pink box; N=1,359) the observed median pLI matched the expected median pLI (Observed 0.03 vs. expected 0.03; empirical p-value: 0.31). For the set of dominant ID genes (blue box; N=444) and ten novel candidate ID genes (green box) the observed median pLI is significantly higher than the expected median pLI (Observed: 0.87 vs. expected: 0.03; empirical p-value $<1 \times 10^{-5}$; Observed 0.99 vs. expected 0.05, respectively). For the dominant 'missense only' genes (with at least 3 missense mutations in the absence of LoF mutations; Orange box; N=21) we observe the highest median pLI of 0.9999 of all evaluated gene sets.

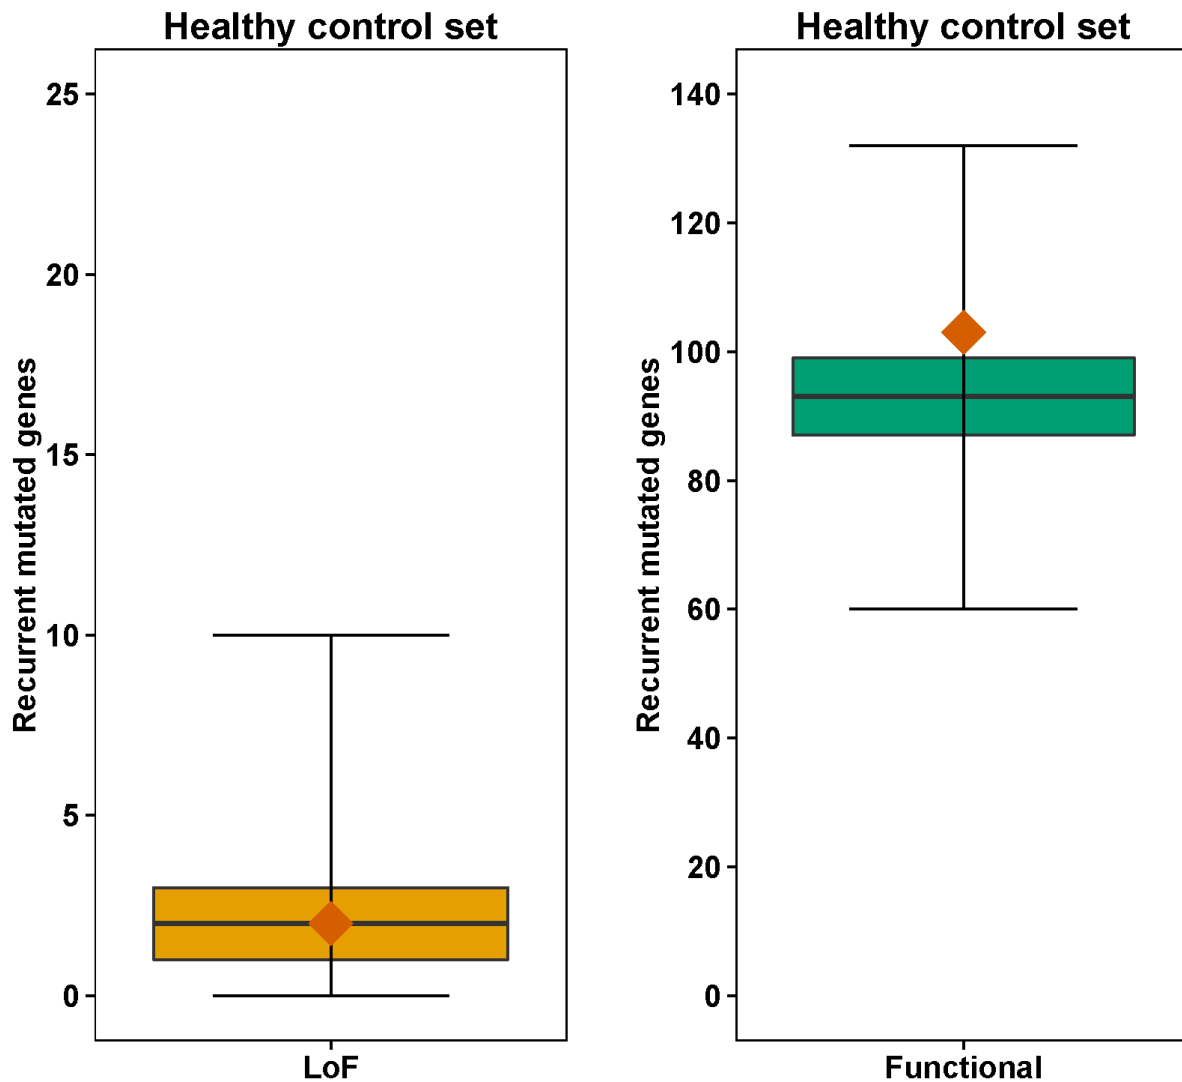

Supplementary Figure 9. Genes enriched for LoF and functional *de novo* mutations in the cohort of 6,206 individuals with neurodevelopmental disease. The y-axis shows the $-\log_{10}(P)$ value of the mutation enrichment. Corrected P-values based on LoF mutations are colored in green and corrected P-values based on functional mutations are colored blue. Only genes with a corrected P-value (LoF, functional, or both) less than the significance threshold (red dotted line, 0.05) are shown.

Legend
Blue Underlined: Novel candidate genes from our study
 * Known NDD gene
 Blue mutation in ID cohort only
 Orange mutation in NDD cohort only (excl. ID)
 Green: mutation in both ID and other NDDs
 Black: Component of complex in which no DNM has been reported in our meta-analysis

Supplementary Figure 10. Schematic representation of a synapse, with special focus on the postsynaptic density (PSD). Proteins playing an essential role in the PSD for signaling cascades and/or receptor trafficking are schematically depicted, as well as the AMPA Receptor (AMPA), NMDA receptor (NMDAR), metabolic Glutamate receptor (mGluR), Calcium and Potassium channels (Ca²⁺ and K⁺ respectively)²². An overlay was made between all DNMs identified in the NDD meta-analysis and the genes playing essential roles in the PSD, as well as with the list of known ID genes. Known ID genes are indicated by an asterisk. For genes in blue, we identified at least one DNM in the ID cohort, whereas the genes in orange were restricted to carry DNMs in the EE, SCZ and/or ASD patients. For genes in green, we identified DNMs in our meta-analysis both the ID and (at least one of the) NDD cohorts. Genes listed in black play a role in e.g. complex formation of the AMPAR or NMDAR, but in have not been identified to carry DNM in our current ID/NDD cohort. Importantly, three of ten genes which we identified as novel candidate ID gene play a role in the PSD and its downstream processes. *DLG4*, encoding post-synaptic density protein 95 (PSD95), is one of the core PSD proteins²³, whereas *RAC1* and *TCF7L2* are important in downstream signaling cascades, including Rho- and Wnt signaling respectively (novel candidate ID are underlined and highlighted in red).

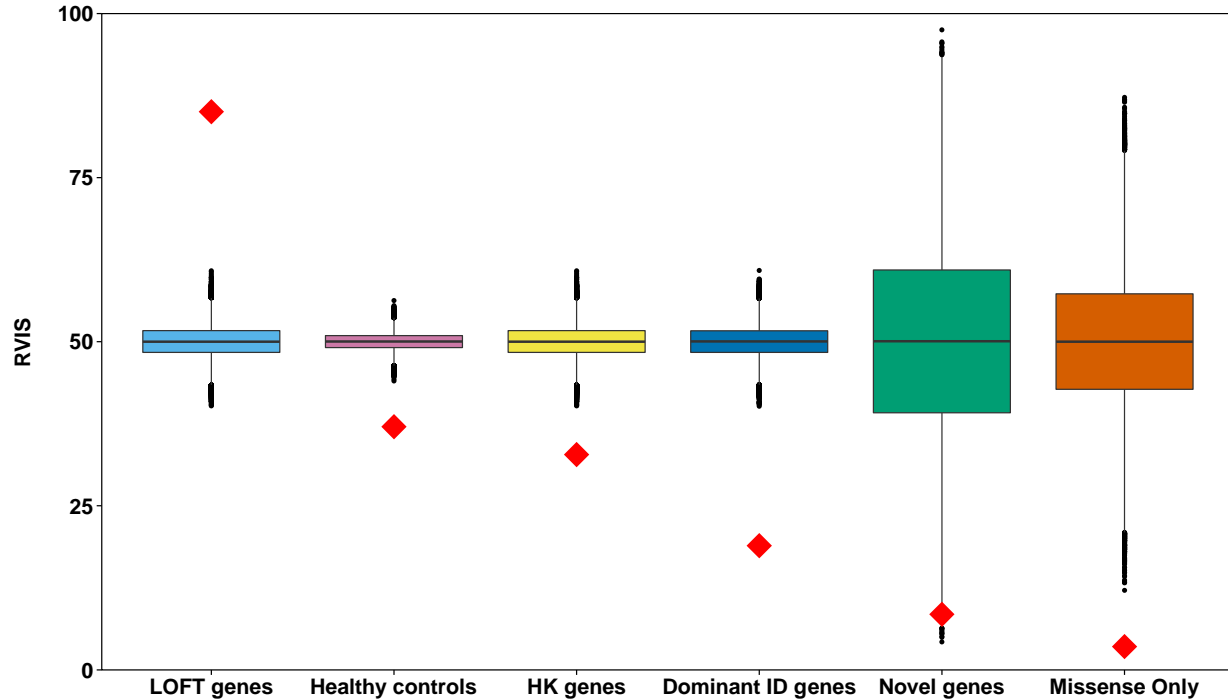

Supplementary Figure 11. Simulations of recurrent mutated genes of the control cohort.

The panels show the distribution of the number of recurrently mutated genes based on 100,000 simulations. The colored boxes indicate the interquartile range; the whiskers indicate the full interval (LoF median: 2, range [0,10]; functional median: 93, range [60,132]) and the orange diamond indicate the observed number of recurrent *de novo* mutated genes in 2,299 healthy controls. For the LoF and the functional categories the observed number of recurrently mutated genes (observed LoF: 2; functional: 103) do not statistically differ from simulations based on the gene specific mutation rates of Samocha *et al.* (LoF empirical P-value: 0.60 ; functional empirical P-value: 0.13).

Supplementary Figure 12. Gene set based evaluation of pLI. The median pLI median per gene set is depicted by a red diamond. Based on 100,000 simulations (**Online methods**) the median pLI for the loss-of-function tolerant (LOFT genes; N= 170) genes was significantly lower (light blue box; observed 9.33×10^{-9} vs. expected 0.03; empirical p-value: $<1 \times 10^{-5}$) than expected. For the healthy control set (Healthy controls; N=1,359) the observed median pLI matched the expected median pLI (pink box; observed 0.03 vs. expected 0.03; empirical p-value: 0.31). For the “house-keeping” (HK; N= 404; yellow box) and dominant ID (Dominant ID genes; N=444; dark blue box) gene sets the observed median pLI is significantly higher than the expected median pLI (Observed: 0.87 vs. expected: 0.03; empirical p-value $<1 \times 10^{-5}$; Observed: 0.95 vs. expected: 0.03; empirical p-value $<1 \times 10^{-5}$, respectively).

Supplementary Figure 13. Gene set based evaluation of RVIS. The median RVIS median per gene set is depicted by a red diamond. Based on the simulations (**Online methods**) we identified a significant higher (light blue box; observed 85.04 vs. expected 50; empirical p-value: $<1 \times 10^{-5}$) median RVIS for the loss-of-function tolerant (LoFT) genes which is in line with the tolerant nature of this gene set. For the healthy control set the observed median RVIS was, to our surprise and unlike the pLI, significantly lower than the expected median RVIS (pink box; observed 37.05 vs. expected 50.00; empirical p-value: $<1 \times 10^{-5}$). For the “house-keeping” and dominant ID gene sets the observed median RVIS is significantly lower than the expected median RVIS (Yellow box; observed: 32.80 vs. expected: 50.00; empirical p-value $<1 \times 10^{-5}$; dark blue box observed: 18.92 vs. expected: 50.00; empirical p-value $<1 \times 10^{-5}$, respectively). The set of ten novel candidate ID genes has an observed median RVIS of 8.47 (green box; empirical p-value = 4.60×10^{-4}). For the 21 dominant ‘missense only’ genes (with at least 3 missense mutations in the absence of LoF mutations) we observe the lowest median RVIS of 3.56 (orange box; empirical p-value $<1 \times 10^{-5}$) again illustrating that those known and novel candidate dominant ID genes that harbor only missense variants are among the most intolerant ID genes.
